1 Introduction

In this document I will discuss my design and modelling considerations for my project's implementation by thorough discussion of each task chosen.

2 Internals

To construct accurate models of each Catalan structure I have, in the file "Internal.hs", created a type class called Catalan which is defined as follows:

```
class Catalan a where
    cons :: a -> a -> a
    decons :: a -> (a, a)
```

In this type class, I have two operators: *cons* and *decons* which are the operators to construct, or compose and deconstruct (or decompose) respectively for each structure.

3 Dyck Paths

To model Dyck paths, I created a module which I named **CatalanStructures.DyckPath**. To represent a Dyck Path I have a list of up-steps and down-steps. Each step is represented by the algebraic data type Step which uses the encoding U for an up-step and D for a down-step. A full Dyck path is represented as a list of steps shown below in the type synonym DyckPath.

```
data Step = U | D deriving (Eq, Show)
type DyckPath = [Step]
```

Next I created an instance of Catalan for the type DyckPath. It is constructed as follows:

```
instance Catalan DyckPath where
    cons alpha beta = mkIndec alpha ++ beta
    decons gamma = stripMaybe $ decompose gamma
```

The function *mkIndec* takes a Dyck path, alpha, and makes an indecomposable DyckPath by prepending a U to the start of alpha then a D to the end of alpha. Then to fully compose our Dyck path with a given alpha and beta we just append beta to mkIndec alpha as is shown above.

Decomposing a Dyck path is the hardest task faced in the design and implementation of the model of a Dyck path. To do this we make a function called *decompose* which takes in a parameter gamma, where gamma is a full Dyck path. Our function *decompose* looks like the following:

```
decompose :: DyckPath -> Maybe (DyckPath, DyckPath)
decompose [] = Nothing
decompose xs@(U:xt) = Just (map fst (init ys), map fst zs)
    where
        0:ht = height xs
        (ys, zs) = span \(_, h) -> h > 0) $ zip xt ht
```

This function starts off by taking a Dyck path and mapping each element of the Dyck path to the height of each element in the half, except from the first element which is disregarded. This is shown by 0:ht. In order to obtain (ys, zs) we use the span function which splits the list into our alpha and beta lists disregarding the down-step which is appended to alpha. To finish off we apply the following to *Just*. We map the first element of the pair to all the elements of ys except the first, and we then map the first element of the pair to zs.

For the height function, it is defined as follows:

```
height :: DyckPath -> [Int]
height = map sum . inits . map dy
    where
        dy U = 1
        dy D = -1
```

Here we start by mapping our encodings of U and D to create a list of 1's and -1's. By applying this to the function inits, it creates a list of partial sums which we then fully add together using "map sum" and we have the height of each element.
